Experiment No.2
Mapping ER/EER to Relational schema model.
Date of Performance:
Date of Submission:

Aim :- Prepare the schema for Relational Model with the ER/ERR diagram, drawn for the identified case study in experiment no.1.

Objective :- To map the Entity Relationship (ER) / Extended Entity-Relationship (EER) Diagram to Relational Model schema and learn to incorporate various schema-based constraints.

Theory:

Mapping an Entity-Relationship (ER) model to a relational database schema involves translating the conceptual model represented in the ER diagram into tables and relationships in a relational database management system (DBMS). Here are the general rules for mapping ER to a schema in a DBMS:

1. Entities to Tables:
 - a. Each entity in the ER diagram corresponds to a table in the relational schema.
 - b. The attributes of the entity become the columns of the table.
 - c. The primary key of the entity becomes the primary key of the table.
2. Relationships to Tables:
 - a. Many-to-Many Relationships:
 - i. Convert each many-to-many relationship into a new table.
 - ii. Include foreign key columns in this table to reference the participating entities.
 - iii. The primary key of this table may consist of a combination of the foreign keys from the participating entities.
 - b. One-to-Many and One-to-One Relationships:
 - i. Represented by foreign key columns in one of the participating tables.
 - ii. The table on the "many" side of the relationship includes the foreign key column referencing the table on the "one" side.
 - iii. The foreign key column typically references the primary key of the related table.
3. Attributes to Columns:
 - a. Each attribute of an entity becomes a column in the corresponding table.
 - b. Choose appropriate data types for each attribute based on its domain and constraints.
 - c. Ensure that attributes participating in relationships are represented as foreign keys when needed.
4. Primary and Foreign Keys:
 - a. Identify the primary key(s) of each table based on the primary key(s) of the corresponding entity.
 - b. Ensure referential integrity by defining foreign keys in tables to establish relationships between them.
 - c. Foreign keys should reference the primary key(s) of related tables.

- d. Ensure that foreign keys have appropriate constraints, such as ON DELETE CASCADE or ON UPDATE CASCADE, to maintain data integrity.
5. Cardinality Constraints:
 - a. Use the cardinality constraints from the ER diagram to determine the multiplicity of relationships in the relational schema.
 - b. Ensure that the constraints are enforced through the appropriate use of primary and foreign keys.
6. Normalization:
 - a. Normalize the schema to minimize redundancy and dependency.
 - b. Follow normalization rules such as First Normal Form (1NF), Second Normal Form (2NF), Third Normal Form (3NF), etc., to ensure data integrity and minimize anomalies.
7. Indexing and Optimization:
 - a. Consider indexing frequently queried columns to improve query performance.
 - b. Evaluate the schema design for optimization opportunities based on query patterns and performance requirements.

Implementation:

The screenshot displays the MySQL Workbench interface. The left sidebar shows the 'SCHEMAS' tree with 'studentdb' selected. The main query editor contains the following SQL code:

```
2 student_name varchar(20),
3 student_id int(2),
4 Address varchar(100),
5 Contact_no int(10),
6 DOB varchar(10)
7 );
8 select * from student;
```

The 'Result Grid' below the query editor shows the following columns: student_name, student_id, Address, Contact_no, DOB. The 'Output' window at the bottom shows the execution log:

#	Time	Action	Message	Duration / Fetch
1	00:17:41	Apply changes to studentdb_schema	Changes applied	
2	01:55:30	create table student (student_name varchar(20), student_id int(2), Address varchar(100), Contact_no int(10), DO...	0 row(s) affected, 2 warning(s): 1681 Integer display width is deprecated and will be removed in a future release. ...	0.109 sec
3	01:56:56	create table student (student_name varchar(20), student_id int(2), Address varchar(100), Contact_no int(10), DO...	Error Code: 1050. Table 'student' already exists	0.015 sec
4	01:57:01	select * from student LIMIT 0, 1000	0 row(s) returned	0.000 sec / 0.000 sec

Conclusion:

1.write definition of relational schema and notations

A relational schema defines the structure of a relational database. It consists of a set of relation schemas, where each relation schema defines the structure of a table (relation) in the database. Each relation schema includes the name of the relation (table) and the names and types of its attributes (columns).

Notations for a relational schema typically include:

Relation (Table) Name: The name of the relation is written at the top, often centered and enclosed in a box or a circle.

Attributes (Columns): Each attribute is listed below the relation name, along with its data type. Attributes are typically written in a column format.

Primary Key: The primary key attribute(s) are underlined to indicate that they uniquely identify each tuple (row) in the relation.

Foreign Key: If an attribute is a foreign key that references another relation, it is typically annotated to indicate the referenced relation and attribute.

Data Types: Data types for each attribute are specified, such as integer, string, date, etc.

Constraints: Any constraints on the attributes, such as NOT NULL or UNIQUE, may be included in the notation.

2.Write various schema-based constraints

Primary Key Constraint: Ensures that a column (or a set of columns) uniquely identifies each record in a table. It enforces the uniqueness and the non-nullability of the specified column(s).

Foreign Key Constraint: Defines a relationship between two tables. It ensures that the values in a column (or a set of columns) of one table match the values in a column (usually the primary key) of another table.

Unique Constraint: Ensures that all values in a column (or a set of columns) are unique across the table.

Unlike the primary key constraint, a unique constraint allows null values, but if a column has a unique constraint, only one null value is allowed.

Check Constraint: Defines a condition that each row must satisfy. It ensures that the values in a column meet specific criteria. For example, a check constraint can be used to ensure that the value in a column is greater than zero.

Not Null Constraint: Ensures that a column cannot have a null value. It requires that every row in the table has a value for that column.

Default Constraint: Specifies a default value for a column. If no value is provided for the column during an insert operation, the default value is used.
